

Computational methods for Bayesian model choice

C.P. ROBERT* D. WRAITH†

July 29, 2009

Abstract

In this note, we shortly survey some recent approaches on the approximation of the Bayes factor used in Bayesian hypothesis testing and in Bayesian model choice. In particular, we reassess importance sampling, harmonic mean sampling, and nested sampling from a unified perspective.

Keywords: Bayesian inference, Bayes factor, importance sampling, nested sampling, Monte Carlo

1 Introduction

The Bayes factor is a fundamental procedure that stands at the core of the Bayesian theory of testing hypotheses, at least in the approach advocated by Jeffreys (1939). (Robert et al. (2009) provides a reassessment of the role of Jeffreys (1939) in setting a formal framework for Bayesian testing) and by Jaynes (2003). Given an hypothesis $H_0 : \theta \in \Theta_0$ on the parameter $\theta \in \Theta$ of a statistical model, with density $f(x|\theta)$, under a compatible prior of the form

$$\pi(\Theta_0)\pi_0(\theta) + \pi(\Theta_0^c)\pi_1(\theta),$$

the *Bayes factor* is defined as the posterior odds to prior odds ratio, namely

$$\begin{aligned} B_{01}(x) &= \frac{\pi(\Theta_0|x)}{\pi(\Theta_0^c|x)} \bigg/ \frac{\pi(\Theta_0)}{\pi(\Theta_0^c)} \\ &= \int_{\Theta_0} f(x|\theta)\pi_0(\theta)d\theta \bigg/ \int_{\Theta_0^c} f(x|\theta)\pi_1(\theta)d\theta. \end{aligned}$$

Since model choice can be considered from a similar perspective, under the Bayesian paradigm (see, e.g., Robert (2001)), the comparison of models

$$\mathfrak{M}_i : x \sim f_i(x|\theta_i), \quad i \in \mathfrak{I},$$

*CEREMADE - Université Paris Dauphine, 75775 Paris, and CREST, ENSAE, France.
Email: xian@ceremade.dauphine.fr

†CEREMADE - Université Paris Dauphine, 75775 Paris, France. Email: darren@ceremade.dauphine.fr

where the family $\mathfrak{I}$ can be finite or infinite, leads to the same quantities,

$$p_i \int_{\Theta_i} f_i(x|\theta_i) \pi_i(\theta_i) d\theta_i \Big/ p_j \int_{\Theta_j} f_j(x|\theta_j) \pi_j(\theta_j) d\theta_j, \quad i, j \in \mathfrak{I}$$

In this short survey, we consider some of the most common Monte Carlo solutions used to approximate a generic Bayes factor or its fundamental component, the *evidence*

$$\mathfrak{Z}_k = \int_{\Theta_k} \pi_k(\theta_k) L_k(\theta_k) d\theta_k,$$

aka the marginal likelihood. Longer entries can be found in Carlin and Chib (1995), Chen et al. (2000), Robert and Casella (2004), or Friel and Pettitt (2008). Note that we do not mention here trans-dimensional methods issued from the revolutionary paper of Green (1995), since our goal here is to demonstrate that within-model simulation allows for the computation of Bayes factors and thus avoids the additional complexity involved in trans-dimensional methods.

2 Importance sampling solutions

While a regular importance sampling approach is feasible towards the approximation of the Bayes factor

$$B_{12} = \frac{\int_{\Theta_1} f_1(x|\theta_1) \pi_1(\theta_1) d\theta_1}{\int_{\Theta_2} f_2(x|\theta_2) \pi_2(\theta_2) d\theta_2},$$

as for instance in

$$\hat{B}_{12} = \frac{n_1^{-1} \sum_{i=1}^{n_1} f_1(x|\theta_1^i) \pi_1(\theta_1^i) / \varpi_1(\theta_1^i)}{n_2^{-1} \sum_{i=1}^{n_2} f_2(x|\theta_2^i) \pi_2(\theta_2^i) / \varpi_2(\theta_2^i)}$$

which relies on importance functions (densities) ϖ_1 and ϖ_2 and on simulations $\theta_1^i \sim \varpi_1$ and $\theta_2^i \sim \varpi_2$, specific solutions targeted toward Bayesian model choice are indeed available and preferable. Most of those solutions fit under the denomination of *bridge sampling* and aim at taking advantage of the connections between the two models under comparison. In fact, when comparing two models with the same complexity (i.e., the same dimension for their respective parameter spaces), it is often possible to find a reparameterisation of both models in terms of some specific moments of the sampling model, like $\mathbb{E}[X]$, so that parameters under both models have a common meaning.

2.1 Bridge sampling

Assuming that the parameters of both models under comparison, θ_1 and θ_2 respectively, thus belong to the same parameter space (i.e., $\Theta_1 = \Theta_2$), a first

solution is to syndicate simulations between both models in order (a) to recycle simulations under one model for the other model and (b) to create correlation between the estimates of the numerator and of the denominator of the Bayes factor in order to improve stability in the estimate. This solution is made clear with the formula of Gelman and Meng (1998)

$$B_{12} \approx \frac{1}{n} \sum_{i=1}^n \frac{\tilde{\pi}_1(\theta_{2i}|x)}{\tilde{\pi}_2(\theta_{2i}|x)},$$

when $\theta_{2i} \sim \pi_2(\theta|x)$, where

$$\begin{aligned} \pi_1(\theta_1|x) &\propto \tilde{\pi}_1(\theta_1|x) \\ \pi_2(\theta_2|x) &\propto \tilde{\pi}_2(\theta_2|x), \end{aligned}$$

as in most Bayesian settings. (An extension to the cases when $\Theta_1 \subset \Theta_2$, including those when the dimension of Θ_1 is smaller than the dimension of Θ_2 , can be easily derived, as shown in Chen et al. (2000). Note that the assumption $\Theta_1 = \Theta_2$ signifies that the representations of both models have been reparameterised in terms of the same moments.)

This is a very special case of the general representation (Torrie and Valleau 1977)

$$B_{12} = \frac{\mathbb{E}_\varphi [\tilde{\pi}_1(\theta)/\varphi(\theta)]}{\mathbb{E}_\varphi [\tilde{\pi}_2(\theta)/\varphi(\theta)]},$$

which holds for any density φ with a sufficiently large support and requires a single sample $\theta_1, \dots, \theta_n$ generated from φ to produce an importance sampling ratio estimate. In that case, a quasi-optimal solution is provided by Chen et al. (2000), namely $\varphi^*(\theta) \propto |\pi_1(\theta) - \pi_2(\theta)|$. The missing normalising constants in both π_1 and π_2 obviously mean that this solution cannot be used *per se*. In fact, considering the very special case when $\pi_1(\theta) = \pi_2(\theta)$ on some region of the parameter space, we see that the solution $\varphi^*(\theta)$ should not be used because it is null on some portion of the support of π_1 and π_2 , thus contradicting a fundamental requirement of importance sampling.

Another extension of this bridge sampling approach can be based on the general representation

$$\begin{aligned} B_{12} &= \frac{\int \tilde{\pi}_2(\theta|x)\alpha(\theta)\pi_1(\theta|x)d\theta}{\int \tilde{\pi}_1(\theta|x)\alpha(\theta)\pi_2(\theta|x)d\theta} \\ &\approx \frac{\frac{1}{n_1} \sum_{i=1}^{n_1} \tilde{\pi}_2(\theta_{1i}|x)\alpha(\theta_{1i})}{\frac{1}{n_2} \sum_{i=1}^{n_2} \tilde{\pi}_1(\theta_{2i}|x)\alpha(\theta_{2i})} \end{aligned}$$

where $\theta_{ji} \sim \pi_j(\theta|x)$, which applies for any positive and integrable function α . Some choices of α do lead to very poor performances of the method in

connection with the harmonic mean approach (Raftery et al. 2007), but there exists a quasi-optimal solution, as provided by Gelman and Meng (1998):

$$\alpha^* \propto \frac{1}{n_1 \pi_1(\theta|x) + n_2 \pi_2(\theta|x)}.$$

Once again, the optimum cannot be used *per se*, since it requires the normalising constants of both π_1 and π_2 . As suggested by Gelman and Meng (1998), an approximate version uses iterative versions of α^* , based on successive iterates of approximations to the Bayes factor. Note that this solution recycles simulations from each posterior, which is quite appropriate since one model is selected via the Bayes factor, instead of using an importance sample common to both approximations. We will see below an alternative representation of the bridge factor that bypasses this difficulty.

2.2 Harmonic means

While using the generic harmonic mean approximation to the marginal likelihood is often fraught with danger (Neal 1994, Chopin and Robert 2007a), the representation (Gelfand and Dey 1994)

$$\mathbb{E}^{\pi_k} \left[\frac{\varphi(\theta_k)}{\pi_k(\theta_k)L_k(\theta_k)} \middle| x \right] = \int \frac{\varphi(\theta_k)}{\pi_k(\theta_k)L_k(\theta_k)} \frac{\pi_k(\theta_k)L_k(\theta_k)}{\mathfrak{Z}_k} d\theta_k = \frac{1}{\mathfrak{Z}_k} \quad (1)$$

holds, no matter what the density $\varphi(\cdot)$ is. This representation is remarkable in that it allows for a direct processing of Monte Carlo or MCMC output from the posterior distribution. In addition, and as opposed to usual importance sampling constraints, the density $\varphi(\theta)$ must have lighter—rather than fatter—tails than $\pi_k(\theta_k)L_k(\theta_k)$ for the approximation of the Bayes factor

$$1 \bigg/ \frac{1}{T} \sum_{t=1}^T \frac{\varphi(\theta_k^{(t)})}{\pi_k(\theta_k^{(t)})L_k(\theta_k^{(t)})}$$

to enjoy finite variance. Therefore, using $\varphi(\theta_k) = \pi_k(\theta_k)$ as in the original harmonic mean approximation (Newton and Raftery 1994) will often result in an infinite variance, as discussed by (Neal 1994). On the opposite, using φ 's with constrained supports derived from a Monte Carlo sample, like the convex hull of the simulations corresponding to the 10% or to the 25% HPD regions—that again is easily derived from the simulations—is both completely appropriate and implementable, as illustrated by Figure 1 for a toy example. In this example, we used the simulations within the HPD region to define an ellipse and consequently a uniform density φ over this ellipse. Since the true “evidence” can be computed analytically, checking the convergence of the harmonic approximation is straightforward. (We warn the reader that this “evidence” cannot be used in a model comparison framework, because it is associated with an improper prior that is not acceptable in testing settings. See DeGroot (1973) or Robert (2001) for more details. Nonetheless, it provides a valid toy example to check the convergence of an integral approximation.)

Figure 1: *(left)* Representation of a Gibbs sample of 10^3 parameters (θ, σ^2) for the normal model, $x_1, \dots, x_n \sim \mathcal{N}(\theta, \sigma^2)$ with $\bar{x} = 0$, $s^2 = 1$ and $n = 10$, under Jeffreys' prior, along with the pointwise approximation to the 10% HPD region (*in darker hues*). *(right)* Evaluation of the approximation of the evidence based on the density φ for the uniform distribution on the ellipse approximating this HPD region.

2.3 Mixture bridge sampling

As noted above, a remarkable feature of the representation (1) is that the derived implementation can directly exploit the output of any MCMC sampler. Another approach introduced in Chopin and Robert (2007b) aims at the same goal and attains the optimal bridge sampler from a completely different perspective. It considers a specific mixture structure as importance function, of the form

$$\tilde{\varphi}(\theta) \propto \omega \pi(\theta) L(\theta) + \varphi(\theta),$$

where $\varphi(\cdot)$ is an arbitrary but fully normalised density. Simulating from this mixture, assuming there already exists an MCMC sampler with stationary distribution $\pi(\theta|x) \propto \pi(\theta)L(\theta)$, is straightforward, thanks to a tailored Gibbs sampler:

Mixture Gibbs sampler

At iteration t

1. Take $\delta^{(t)} = 1$ with probability

$$\omega_1 \pi_k(\theta_k^{(t-1)}) L_k(\theta_k^{(t-1)}) \Big/ \left(\omega_1 \pi_k(\theta_k^{(t-1)}) L_k(\theta_k^{(t-1)}) + \varphi(\theta_k^{(t-1)}) \right)$$

and $\delta^{(t)} = 2$ otherwise;

2. If $\delta^{(t)} = 1$, generate $\theta_k^{(t)} \sim \text{MCMC}(\theta_k^{(t-1)}, \theta_k)$ where $\text{MCMC}(\theta_k, \theta'_k)$ denotes an arbitrary MCMC kernel associated with the posterior $\pi_k(\theta_k|x) \propto \pi_k(\theta_k)L_k(\theta_k)$;
3. If $\delta^{(t)} = 2$, generate $\theta_k^{(t)} \sim \varphi(\theta_k)$ independently

The simulation step 1. selecting between both components of the mixture is not only allowing for simulation from this mixture, but it also does provide a direct estimate to the evidence. Indeed, the Rao-Blackwellised estimate

$$\hat{\xi} = \frac{1}{T} \sum_{t=1}^T \omega_1 \pi_k(\theta_k^{(t)}) L_k(\theta_k^{(t)}) \Big/ \omega_1 \pi_k(\theta_k^{(t)}) L_k(\theta_k^{(t)}) + \varphi(\theta_k^{(t)}),$$

converges to $\omega_1 \mathfrak{Z}_k / \{\omega_1 \mathfrak{Z}_k + 1\}$ and we can thus deduce

$$\hat{\mathfrak{Z}}_{3k} = \frac{1}{\omega_1} \frac{\sum_{t=1}^T \omega_1 \pi_k(\theta_k^{(t)}) L_k(\theta_k^{(t)}) \Big/ \omega_1 \pi_k(\theta_k^{(t)}) L_k(\theta_k^{(t)}) + \varphi(\theta_k^{(t)})}{\sum_{t=1}^T \varphi(\theta_k^{(t)}) \Big/ \omega_1 \pi_k(\theta_k^{(t)}) L_k(\theta_k^{(t)}) + \varphi(\theta_k^{(t)})}.$$

We have thus recovered the optimal bridge sampling estimate from this different perspective, akin to Bartolucci et al. (2006), that is more in line with reversible jump trans-dimensional schemes than regular importance sampling. The only modification compared with the original version is that the sequence $(\theta_k^{(t)})$ is generated from the mixture for both the numerator and the denominator. Figure 2 shows that, for the toy example introduced in Figure 1, the harmonic mean approximation does as well as the optimal bridge sampling solution.

3 Nested sampling

This method introduced in Skilling (2006, 2007) (although an earlier version can be found in Burrows (1980)) produces a very specific type of importance sampling based on constrained simulations from the prior distribution. While more details descriptions are available in the above reference and Chopin and Robert (2007b) (as well as a full convergence assessment in the later paper), let us recall here that nested sampling is based on the one-dimensional representation

$$\mathfrak{Z} = \mathbb{E}^\pi[L(\theta)] = \int_0^1 \varphi(x) dx$$

of the evidence, when

$$\varphi^{-1}(l) = P^\pi(L(\theta) > l)$$

is the survival probability function associated with the likelihood. The approximation of $\mathfrak{Z}$ by a Riemann sum:

$$\hat{\mathfrak{Z}} = \sum_{i=1}^N (x_{i-1} - x_i) \varphi(x_i)$$

Figure 2: For the same setting as Figure 1, *(left)* Evaluation of the bridge sampling approximation of the evidence based on the mixture $\tilde{\varphi}$ when the density φ corresponds to the uniform distribution on the ellipse approximating the same HPD region as in Figure 1, using a value of ω equal to one-tenth of the true evidence; *(right)* boxplot comparison of the variations of both approaches based on 100 Monte Carlo replicas with samples of size 10^4 . On both graphs, the true evidence is represented by the horizontal dotted line.

where the x_i 's are either deterministic, e.g. $x_i = \exp\{-i/N\}$, or random, also allows for the representation

$$\hat{\mathfrak{Z}} = \sum_{i=0}^{N-1} \{\varphi(x_{i+1}) - \varphi(x_i)\}x_i$$

which is a special case of

$$\hat{\mathfrak{Z}} = \sum_{i=0}^{N-1} \{L(\theta_{(i+1)}) - L(\theta_{(i)})\}\pi(\{\theta; L(\theta) > L(\theta_{(i)})\}) \quad (2)$$

where $\dots L(\theta_{(i+1)}) > L(\theta_{(i)}) \dots$. (This can be seen as the Lebesgue version of the Riemann's sum, the triangulation being on the second axis instead of the first axis.) Since φ is rarely available in closed form, the nested sampling algorithm relies on an estimate of $\varphi(x_i)$ or, equivalently, of $\pi(\{\theta; L(\theta) > L(\theta_{(i)})\})$:

Nested sampling algorithm

Start with N values $\theta_1, \dots, \theta_N$ sampled from π

At iteration i ,

1. Take $\varphi_i = L(\theta_k)$, where θ_k is the point with smallest likelihood in the pool of θ_i 's

2. Replace θ_k with a sample from the prior constrained to $L(\theta) > \varphi_i$: the current N points are sampled from prior constrained to $L(\theta) > \varphi_i$.

In terms of the representation (2), this amounts to use the approximation

$$\hat{\pi}(\{\theta; L(\theta) > L(\theta_{(i)})\})/\pi(\{\theta; L(\theta) > L(\theta_{(i-1)})\}) = (N-1)/N.$$

As discussed in Evans (2007) and Chopin and Robert (2007c), the dominating term in the approximation is the stochastic part that converges at $O(\sqrt{n})$ speed. The method thus formally compares with those mentioned in the previous section. At a more practical level, nested sampling can be interpreted as an importance sampling technique where, instead of simulating a whole sample from the prior distribution, $\pi(\theta)$, and approximating the evidence by

$$\frac{1}{N} \sum_{i=1}^N L(\theta_i),$$

which is usually inefficient, points $\theta_{(i)}$ are successively sampled from the prior restricted to higher and higher levels of the likelihood, with decreasing weights

$$\frac{1}{N} \left(1 - \frac{1}{N}\right)^{i-1}.$$

To illustrate the comparison with a standard importance sampling approximation, we now consider an artificial example based on the likelihood of a twisted normal distribution (first introduced in (Haario et al. 1999) as a benchmark for adaptive MCMC schemes) in two dimensions with covariance matrix $\Sigma = \text{diag}(\sigma_1^2, 1)$. The “twist” is due to considering the transform $\theta'_2 = \theta_2 + \beta(\theta_1^2 - \sigma_1^2)$, which leads to a sharp bend in the likelihood contours, as shown in Figure 3. Since the Jacobian of the twist is equal to 1, the density is thus defined as:

$$\psi(\theta_1, \theta_2) = (\theta_1, \theta_2 + \beta(\theta_1^2 - \sigma_1^2)) \sim \mathcal{N}_2(0, \Sigma).$$

If we consider β and σ_1^2 as known, the appeal of this example is in integrating over the parameters θ_1 and θ_2 with priors $\pi(\theta_1, \theta_2)$. The toy evidence can thus be represented as

$$\mathfrak{Z}_1 = \int \psi(\theta_1, \theta_2) \pi(\theta_1, \theta_2) d\theta$$

For the example that we consider, we fix $\beta = 0.03$, $\sigma_1^2 = 100$ (as represented in Figure 3) and we use flat priors on θ_1 in $(-40, 40)$ and on θ_2 also on $(-40, 40)$. (The prior square is chosen arbitrarily to allow all possible values and still to retain a compact parameter space. Furthermore, a flat prior allows for an easy implementation of nested sampling since the constrained simulation can be implemented via a random walk move, as pointed out in Skilling (2006).). Integrating the likelihood over this region of the parameter space presents a challenging problem for any approach as the coverage of the tails of the twisted

Figure 3: Contours (at the levels 68%, 95% and 99.9%) of the likelihood of the twisted normal model for $\beta = .03$, $\sigma_1^2 = (100)$.

normal distribution can be difficult or even impossible to capture. (This point is discussed at length in Wraith et al. (2009).)

In this toy example, the two-dimensional nature of the parameter space does allow for a numerical integration of $\mathfrak{Z}_1$, thus producing a reference value, based on a Riemann approximation of the integral and a grid of 1000×1000 points in the $(-40, -40) \times (40, 40)$ square (an adaptive quadrature approach was also used as a check). This approach leads to a stable evaluation of $\mathfrak{Z}_1$ that can be reliably taken as the reference against which we test alternative approximation methods.

The comparison is here restricted to a standard nested sampling algorithm derived from Skilling (2006) and a population Monte Carlo (PMC) mixture importance sampler constructed in Wraith et al. (2009) for this benchmark problem and introduced in Cappé et al. (2008) in a general framework. Briefly, this importance sampling approach is adaptive as it consists of modifying the parameters of the importance function (a mixture density), bringing it closer to the posterior density over a small number of iterations. The proximity is measured in terms of the Kullback divergence between the posterior density and importance function, since utilising an integrated EM approach ensures that the divergence successively decreases at each iteration. While this adaptive importance sampler derives a proposal φ to simulate from the (pseudo-)posterior $\psi(\theta_1, \theta_2)\pi(\theta_1, \theta_2)$, it can obviously provide in addition an approximation of the marginal likelihood $\mathfrak{Z}_1$. (We stress that any importance sampler used in this setting offers this facility of providing an approximation of both the evidence and of its variability.)

For comparison purposes, the PMC approach uses 5000 simulated points per iteration over a total of 10 iterations and then a final sample of 50000 points, simulated from the “optimal” importance sampling function obtained through the PMC sequence. The importance function to be optimised consists of a mixture of 9 multivariate Student t’s with 9 degrees of freedom for each component. For the initial values of the importance function, components of

Figure 4: Comparison of nested sampling with PMC over 100 simulation runs for (*left*) Evidence estimation; (*centre*) $\mathbb{E}[\theta_1]$ estimation; (*right*) $\mathbb{E}[\theta_2]$ estimation. The true value is represented as an horizontal dotted line.

the mixture are located randomly in different directions slightly away from 0: the mean of the components are drawn from a bivariate Gaussian distribution with mean 0 and covariance equal to $\Sigma_0/5$, where Σ_0 is a diagonal matrix with diagonal entries (200, 50). In parallel, we run the nested sampling algorithm with $N = 1000$ initial points, reproducing the implementation of Skilling (2006), using 50 steps of a random walk in (θ_1, θ_2) constrained by the likelihood boundary to produce the next value, based on the contribution of the current value of (θ_1, θ_2) to the approximation of $\mathfrak{Z}_1$. The step size (ie. the variance) in the random walk is 0.1 and the process is repeated (iterated) 10,000 times (and monitored) to ensure a definitive completion of the accumulation of $\mathfrak{Z}_1$. Alternative scenarios, including changes to the number of points N , to the number of steps and to the step size were explored to assess the sensitivity of the results to the values set, but they did not lead to an improvement in the results. To assess the variability of the results, 100 simulation runs for both PMC and nested sampling algorithms have been used.

Figure 4 summarises our results for PMC compared with nested sampling over the 100 simulation runs for evaluation of the evidence $\mathfrak{Z}_1$ and of the posterior mean for θ_1 ($\mathbb{E}[\theta_1]$) and θ_2 ($\mathbb{E}[\theta_1]$), since the outcome of a nested sampling run can be utilised as any importance sampling output. Those results suggest that nested sampling exhibits a slight upward bias for the evaluation of the evidence (a point also noted in Chopin and Robert (2007b)) while it approximately produces the same numerical value for the estimates of $\mathbb{E}[\theta_1]$ and of $\mathbb{E}[\theta_2]$, albeit with a greater variability.

4 Comments

Various importance sampling strategies have been proposed recently that explicitly target the evidence. While there is no clear winner emerging from the comparison, we conclude that the bridge sampling strategy remains a reference

in this domain, but also that the harmonic version of Gelfand and Dey (1994), Bartolucci et al. (2006), Chopin and Robert (2007b) may produce valuable approximations if the empirical HPD regions are exploited in the way described in the current paper.
